Abstract

We measure the cosmic star formation history out to $z = 1.3$ using a sample of 918 radio-selected star forming galaxies within the 2 deg² COSMOS field. To increase our sample size, we combine 1.4 GHz flux densities from the VLA-COSMOS catalogue with flux densities measured from the VLA-COSMOS radio continuum image at the positions of $I < 26.5$ galaxies, enabling us to detect 1.4 GHz sources as faint as 40 μ Jy. We find radio measurements of the cosmic star formation history are highly dependent on sample completeness and models used to extrapolate the faint end of the radio luminosity function. For our preferred model of the luminosity function, we find the star formation rate density increases from 0.019 $M_{\odot} \text{ yr}^{-1} \text{ Mpc}^{-3}$ at $z \sim 0.225$ to 0.104 $M_{\odot} \text{ yr}^{-1} \text{ Mpc}^{-3}$ at $z \sim 1.1$, which agrees to within 33% of recent UV, IR and 3 GHz measurements of the cosmic star formation history.

Keywords: galaxies: evolution – galaxies: luminosity function – galaxies: star formation

1 INTRODUCTION

The star formation rate density (SFRD) quantifies the star formation rate (SFR) per unit volume at a given redshift, and has been measured at a variety of wavelengths (e.g. UV, IR, optical emission lines). Previous SFRD measurements at radio wavelengths are qualitatively similar to SFRDs measured with UV and IR data (Madau & Dickinson, 2014, and references therein), although individual $z \sim 0$ radio luminosity functions can differ from each other by a factor of 3 at low radio powers (e.g. Mauch & Sadler, 2007, and references therein). All measurements of the cosmic star formation history (CSFH) at $z < 3$ follow a broadly similar trend, with SFRD declining by a factor of roughly 20 since its peak at $z \sim 2.5$. For individual galaxies, SFRs determined with different indicators can often differ by factors of 2 or more, and inconsistencies as large as a factor of 10 are not uncommon (e.g. Hopkins et al., 2003). Consequently, achieving precise measurements of the CSFH with different SFR indicators requires large sample sizes to mitigate both cosmic variance and uncertainties on individual SFR measurements. At $z < 1.5$ recent measurements of the CSFH agree with each other to within ~ 0.2 dex (Madau & Dickinson, 2014, and references therein).

By using radio data to measure the CSFH, it is pos-

sible to present a complementary view to the UV and IR surveys, which make up the bulk of high- z SFRDs (Madau & Dickinson, 2014). The advantage of radio observations is that they provide SFRs unbiased by dust but with the disadvantage of potentially including contamination from active galactic nuclei (AGNs). These AGNs have to be removed to measure a reliable radio SFRD, which can then be compared to SFRDs derived from other wavelengths and models.

The first attempts to calculate the CSFH from radio surveys used small samples of star forming (SF) galaxies, due to the relatively shallow data and/or small survey areas available at the time, and thus these studies had large uncertainties. One of the first measurements of the radio CSFH, by Haarsma et al. (2000), found that the SFRD has declined by an order of magnitude since $z \sim 1.6$, but their best sample contained just 37 radio sources. Over the subsequent decade the radio sample sizes increased, with Seymour et al. (2008) measuring the CSFH with 269 $z < 3$ star forming galaxies and Smolčić et al. (2009) using 340 $z < 1.3$ star forming galaxies in the COSMOS field. The most recent study of the radio CSFH, by Novak et al. (2017), uses 5806 $z < 5.7$ star forming galaxies with 3 GHz flux densities from the VLA-COSMOS 3 GHz Large Project. Despite the large expansion in the sample sizes over the past two decades, the radio luminosity function and CSFH can still be adequately modelled with pure luminosity

evolution (Novak et al., 2017), as previously found by Hopkins (2004).

Previous measurements of the radio CSFH have largely used blind radio survey source catalogues. Such catalogues require conservative signal-to-noise (S/N) thresholds to avoid being swamped by large numbers of spurious sources. For example, searching images containing a total of 250 million pixels with a S/N threshold of 4 could produce as many as ~ 8000 false detections. As the number of spurious sources scales with the number of pixels, lower S/N thresholds can be used if one limits detections and measurements to positions of optically identified galaxies. This approach may be particularly useful for studies exploiting the new generation of deep radio continuum surveys in combination with optical galaxy surveys (e.g., Norris et al., 2011; da Cunha et al., 2017), enabling significant expansion of sample sizes. In this letter we utilise this approach to detect sources down to a signal-to-noise of 3 and to measure the CSFH.

We present the $z < 1.3$ CSFH measured by combining the COSMOS $I < 26.5$ object catalogue with the 1.4 GHz VLA-COSMOS survey. We exploit a combination of catalogued radio sources and new flux density measurements at the positions of optical galaxies to reliably measure 1.4 GHz flux densities as faint as $S_{1.4} = 40 \mu\text{Jy}$. We use AB magnitudes throughout, the Salpeter (1955) initial mass function (IMF), and adopt a flat nine-year WMAP cosmology with $H_0 = 69.32 \text{ km s Mpc}^{-1}$, $\Omega_M = 0.29$ and $\Omega_\Lambda = 0.71$ (Bennett et al., 2013). We assume the radio synchrotron spectrum is approximated by $S_\nu \propto \nu^{-0.7}$.

2 SAMPLE

We selected our sample using a combination of COSMOS optical and radio catalogues. The main COSMOS optical catalogue is from Ilbert et al. (2015), and it contains over 2 million sources with $I < 26.5$. This was cross-matched to both the Lilly et al. (2007) spectroscopic redshift catalogue and the COSMOS2015 photometric redshift catalogue (Laigle et al., 2016). When available, we use spectroscopic redshifts in preference to photometric redshifts.

Our principal radio catalogue is from the 1.4 GHz VLA-COSMOS survey (Schinnerer et al., 2010), which imaged 2 deg^2 centred on $10:00:28.60 +02:12:21.00$ with an angular resolution of $2.5''$. In the central $50' \times 50'$ the depth is $S_{1.4} = 12 \mu\text{Jy}$ RMS, increasing to an RMS of $S_{1.4} = 34 \mu\text{Jy}$ at the edges. The accompanying source catalogue includes sources with $S/N > 4\sigma$. The VLA-COSMOS deep radio catalogue of Schinnerer et al. (2010) does not include the suite of COSMOS multiwavelength data, so magnitudes and redshifts were obtained by finding the nearest cross-matches in the merged optical, spectroscopic redshift and photometric redshift catalogue.

If we exclude multicomponent sources from the Schinnerer et al. (2010) radio catalogue, as they are likely to be AGNs, then we have 2732 radio sources. When we match these 2732 sources to the optical catalogue, we find that just 233 (9%) of the radio catalogue sources lack optical counterparts. For radio sources fainter than $100 \mu\text{Jy}$, we find the percentage without optical counterparts rises to just 11%. Using the Brown et al. (2017) nearby galaxy sample, we find star forming galaxies have i -band to 1.4 GHz flux density ratios that range from 0.1 to 30, so we expect low redshift $S_{1.4} = 40 \mu\text{Jy}$ star forming galaxies to be brighter than $i = 22.4$. At $z = 1.15$ the i -band and 1.4 GHz correspond to u -band and 3.0 GHz respectively, and we find the Brown et al. (2017) nearby galaxy sample u -band to 3.0 GHz flux density ratios range from 0.05 to 20, so we expect $z \sim 1.15$ $S_{1.4} = 40 \mu\text{Jy}$ star forming galaxies to be brighter than $i = 23.2$. We thus conclude that the bulk of the radio sources without $i < 26.5$ optical counterparts are AGNs or $z > 1.3$ galaxies.

Our sample uses a combination of the Ilbert et al. (2015) optical catalogue and the VLA-COSMOS deep catalogue of Schinnerer et al. (2010), supplemented by 1.4 GHz flux densities measured at the positions of the optical galaxies. For every optical galaxy we measured a 1.4 GHz flux density per beam using the pixel in the VLA-COSMOS images that corresponds to the optical position, although we only use this flux density if a match to the Schinnerer et al. (2010) catalogue is unavailable. (This assumes we are mostly observing radio point sources, which is a reasonable approximation for star forming galaxies across the bulk of our redshift range, as $2.5''$ corresponds to 8.3 kpc at $z = 0.2$.) For the subsequent analyses we retain galaxies with 1.4 GHz $S/N > 3\sigma$ and $S_{1.4} \geq 40 \mu\text{Jy}$ measured in the Schinnerer et al. (2010) catalogue and/or measured directly from the VLA-COSMOS images.

To measure the radio CSFH we selected a sample of $z < 1.3$ star forming galaxies with radio flux densities above 3σ , using regions that have two or more VLA pointings in the VLA-COSMOS survey (Fig. 2 from Schinnerer et al., 2010). Radio sources with $S_{1.4} > 50 \text{ mJy}$ that cause artifacts in the VLA-COSMOS deep image were identified and all the galaxies in these regions were removed. This reduces our central area, where the depth is $S_{1.4} = 40 \mu\text{Jy}$, to 0.72 deg^2 , while our (shallower) total area is 0.96 deg^2 . We also visually cross checked close pairs of radio sources and removed instances of single sources being spuriously identified as multiple objects. We then split our sample into star forming galaxies and AGNs using the passive galaxy colour criterion illustrated in Figure 1 and a modified Stern et al. (2005) infrared AGN selection criterion (that does not cut into the galaxy locus). This leaves us with a sample containing 918 $z < 1.3$ star forming galaxies, of which 374 were not contained within the Schinnerer

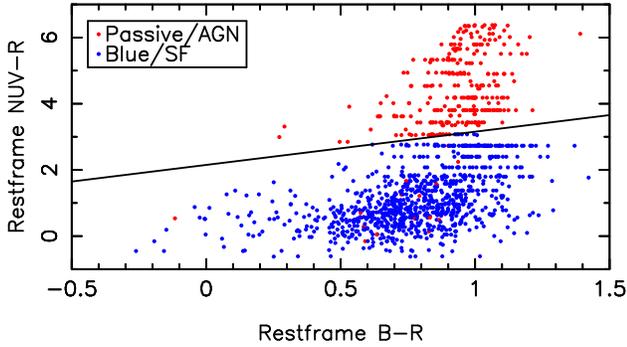

Figure 1. The restframe colours of our final sample of 1218 radio selected galaxies, illustrating the loci of SF and passive galaxies. We use the empirical criterion shown above in combination with a modified Stern et al. (2005) mid-infrared wedge to split the sample into 918 star forming galaxies and 300 AGNs. (Some quantization and aliasing of the absolute magnitudes is an artifact from the COSMOS2015 photometric redshift catalogue.)

et al. (2010) VLA-COSMOS deep catalogue. Of the 918 $z < 1.3$ star forming galaxies with $S_{1.4} > 40 \mu\text{Jy}$, 883 (96%) are brighter than $I = 25$, consistent with incompleteness due to our $I = 26.5$ magnitude limit being negligible.

Photometric redshift uncertainties for $23 < I < 24$ $z \sim 1$ star forming galaxies are 4.4% (Laigle et al., 2016), which propagate through to individual radio powers having uncertainties of 9% (while brighter star forming galaxies have smaller uncertainties). We use spectroscopic redshifts in preference to photometric redshifts when possible, and they are available for 37% of the $I < 22$ star forming galaxies.

3 THE 1.4 GHz RADIO LUMINOSITY FUNCTION

We have measured the radio luminosity function for four different redshift bins using the standard $1/V_{max}$ method (Schmidt, 1968). To achieve this, our sample was split into four redshift ranges ($0.1 \leq z < 0.35$, $0.35 \leq z < 0.6$, $0.6 \leq z < 0.9$ and $0.9 \leq z < 1.3$) and then into bins of $1/3$ dex in luminosity. Luminosity limits and survey volumes are constrained by the flux density limits of $S_{1.4} = 40 \mu\text{Jy}$ for the central region and $S_{1.4} = 60 \mu\text{Jy}$ for the outer $350''$. To keep the sample complete these flux limits were taken into account when calculating the redshift range, effective area and resulting V_{max} for each bin. As a result, of the 918 star forming galaxies in our sample, 525 meet our area and redshift dependent luminosity criteria.

In Figure 2 and Table 1 we present the 1.4 GHz luminosity functions for our four redshift bins, including uncertainties determined using Poisson statistics (e.g., Gehrels, 1986). However, we caution that for the inner region of the sample the $0.10 < z < 0.14$ and

$0.10 < z < 0.20$ redshift slices have cosmic variance uncertainties of 74% and 43% respectively (determined with the method of Driver & Robotham, 2010). For comparison in Figure 2 we also show the VLA-COSMOS 1.4 and 3.0 GHz luminosity functions previously measured by Smolčić et al. (2009) and Novak et al. (2017), adopting a spectral index of -0.7 for frequency conversions. Compared to the Smolčić et al. (2009) 1.4 GHz luminosity functions, we find higher space densities at all but the very highest radio luminosities. This is expected, as 41% of our star forming galaxies were not included in the VLA-COSMOS radio source catalogue of Schinnerer et al. (2010). We find better agreement with the recent luminosity functions of Novak et al. (2017), who also measure higher space densities than Smolčić et al. (2009), using a sample selected from 3 GHz imaging of the COSMOS field (with an RMS of $S_{3.0} = 2.3 \mu\text{Jy}$ per beam).

To model the luminosity function we use the models of Condon (1989) and Condon et al. (2002) with pure luminosity evolution added. Our preferred model is Condon et al. (2002), which is based on the luminosity function determined with 1966 $m_p < 14.5$ galaxies from the Uppsala General Catalogue (Nilson, 1973) with counterparts in the NRAO VLA Sky Survey (Condon et al., 1998). However, we also make use of the Condon (1989) model as it has been used by other studies during the past decade, including Smolčić et al. (2009), and it illustrates the impact of model assumptions on our results and those from the literature. The dashed lines in Figure 2 illustrate the $z = 0$ Condon et al. (2002) luminosity function while the solid lines show fits of the Condon et al. (2002) model to our data under the assumption of pure luminosity evolution. When we approximate the observed luminosity evolution with $L(z) \propto (1+z)^Q$, we find $Q = 3.10 \pm 0.06$.

4 THE COSMIC STAR FORMATION HISTORY

To measure the SFRD and CSFH, we first determined each galaxy’s SFR using the 1.4 GHz radio luminosity and the calibration of Bell (2003):

$$\psi[M_{\odot}\text{yr}^{-1}] = \begin{cases} 5.52 \times 10^{-22} L_{1.4\text{GHz}}, & L_{1.4\text{GHz}} > L_c \\ \frac{5.52 \times 10^{-22}}{0.1+0.9(L_{1.4\text{GHz}}/L_c)^{0.3}} L_{1.4\text{GHz}}, & L_{1.4\text{GHz}} \leq L_c \end{cases} \quad (1)$$

where $L_c = 6.4 \times 10^{21} \text{ W Hz}^{-1}$. This SFR calibration has been used by both Smolčić et al. (2009) and Novak et al. (2017), and is comparable to recent calibrations by Boselli et al. (2015) and Brown et al. (2017) for $< L^*$ galaxies. We then used the $1/V_{max}$ method (Schmidt, 1968), with the SFR divided by the volume in which the galaxy could be detected, to find the SFRD contribution for each galaxy. The sum of each detected galaxy’s contribution to the SFRD gives a lower limit to the SFRD,

Table 1 1.4 GHz radio luminosity functions for VLA-COSMOS star forming galaxies.

Redshift range	Luminosity range $\log_{10}(\text{W Hz}^{-1})$	Number of galaxies	Volume (Mpc^{-3})	LF ($\text{Mpc}^{-3} \text{dex}^{-1}$)
$0.10 \leq z < 0.14$	21.33-21.67	3	7.42×10^3	$1.21 \pm_{0.57}^{1.36} \times 10^{-3}$

$0.90 \leq z < 1.30$	24.33-24.67	5	2.66×10^6	$5.64 \pm_{2.17}^{4.29} \times 10^{-6}$

^aThis volume includes the outer region with the shallower flux density limit.

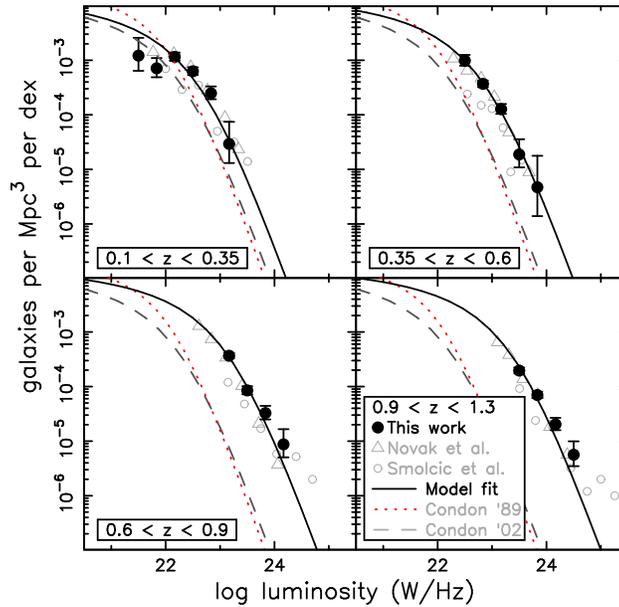

Figure 2. 1.4 GHz luminosity functions of star forming galaxies. The dashed line is the Condon et al. (2002) local luminosity function, while the solid line is this function fitted to our data under the assumption of pure luminosity evolution. The red dotted line is the deprecated Condon (1989) local luminosity function, which overestimates the number of galaxies at low radio luminosities. We measure a higher space density of low luminosity galaxies than Šmolčić et al. (2009), but are in agreement with the deeper 3 GHz measurements of Novak et al. (2017).

as it does not include star forming galaxies fainter than our radio flux limits. These lower limits for the CSFH are shown with arrows in Figure 3.

To obtain an SFRD that includes galaxies fainter than our flux density limits, we have modelled our data with the Condon (1989) and Condon et al. (2002) radio luminosity function models with the addition of pure luminosity evolution where $L(z) \propto (1+z)^Q$. We choose to not use the newer radio luminosity function model of Mauch & Sadler (2007) as their sample is incomplete at low luminosities due to the surface brightness limits of the 2MASS survey. While the Condon (1989) model has been used by some studies, we find it is a relatively poor fit to our data and it overestimates the $z \sim 0$ SFRD relative to recent radio luminosity functions (Condon et al., 2002; Mauch & Sadler, 2007; Mao et al., 2012). Our preferred model is thus Condon et al. (2002), which approximates our data well, as illustrated by Figure 2.

We determined SFRDs by integrating $\int \psi(L)\Phi_B(L)dL$, where $\psi(L)$ is the star formation rate from Equation 1 and $\Phi_B(L)$ is the radio luminosity function model. The resulting SFRDs and (for comparison) those from Smolčić et al. (2009) are provided in Table 2 and Figure 3. As Figure 3 illustrates, our SFRD measurements depend on the luminosity function model, with the impact increasing with increasing redshift. At $0.10 \leq z < 0.35$ our SFRD measurements have little dependence on the luminosity function model, but at $0.90 \leq z < 1.30$ the Condon (1989) model provides an estimate of the SFRD that is 65% higher than the estimate provided using the Condon et al. (2002) model.

As expected, we measure a systematically higher CSFH than Smolčić et al. (2009) when the same luminosity function model is used. However, it should be noted that Smolčić et al. (2009) does agree well with the literature when the Condon (1989) model of the luminosity function is used, as this model’s overestimate of the number of faint sources compensates for sample incompleteness. Our SFRD measurements, using the preferred Condon et al. (2002) model, agree well with recent UV, IR and 3 GHz studies (Cucciati et al., 2012; Gruppioni et al., 2013; Novak et al., 2017), with the possible exception of $0.90 \leq z < 1.30$, where we measured a higher SFRD than Novak et al. (2017). Using the preferred Condon et al. (2002) model. We find the SFRD can be approximated by $0.0109 \times (1+z)^{3.10 \pm 0.06} M_\odot \text{ yr}^{-1} \text{ Mpc}^{-3}$, which implies SFRD has declined by a factor of ten from $0.90 \leq z < 1.30$ to $z \sim 0$.

5 DISCUSSION

Given both we and Smolčić et al. (2009) measure the 1.4 GHz luminosity function and CSFH using the COSMOS field, it is useful to explore why our results differ significantly from those of Smolčić et al. (2009). First,

there are some differences in the radio catalogues used, with Smolčić et al. (2009) using the Schinnerer et al. (2007) catalogue whereas we are using the deeper Schinnerer et al. (2010) catalogue. The most significant differences, however, arise from our addition of new flux densities measured at the positions of optical galaxies allowing the use of a lower S/N threshold. Smolčić et al. (2009) imposed $S/N > 5\sigma$ and $S_{1.4} \geq 52.5 \mu\text{Jy}$, whereas we imposed $S/N > 3\sigma$ and $S_{1.4} \geq 40.0 \mu\text{Jy}$. Our sample contains 308 star forming galaxies with $40.0 \mu\text{Jy} \leq S_{1.4} < 52.5 \mu\text{Jy}$.

Given the large differences in sample size, are the radio flux densities measured at optical galaxy positions valid? We find flux densities (per beam) measured at optical galaxy positions are typically $\sim 90\%$ of the catalogued flux densities (per beam) for sources with $S_{1.4} \lesssim 100 \mu\text{Jy}$. Visual inspection of the 1.4 GHz VLA-COSMOS image shows that uncatalogued radio sources with $S/N > 3$ appear to be real radio sources rather than artifacts. This includes a limited number of $S_{1.4} \sim 100 \mu\text{Jy}$ sources, which are significantly brighter than the notional limits of the VLA-COSMOS catalogs (Schinnerer et al., 2007, 2010), which suggests there are (rare) failures of source detection algorithms on relatively bright sources (whose flux densities can otherwise be accurately measured).

A final cross check of the validity of our approach is by comparison to previous literature. Our results agree well with recent measurements of the CSFH using UV, IR and 3 GHz data (e.g., Cucciati et al., 2012; Gruppioni et al., 2013; Novak et al., 2017). We find the evolution of the SFRD at $z < 1.3$, determined by fitting our SFRD measurements and Condon et al. (2002), is approximated by $0.0109 \times (1+z)^{3.10 \pm 0.06} M_\odot \text{ yr}^{-1} \text{ Mpc}^{-3}$. For comparison, Novak et al. (2017) find radio luminosity function can be approximated by pure luminosity evolution where $L(z) \propto (1+z)^{(3.16 \pm 0.2 - (0.32 \pm 0.07)z)}$, which is similar to our results at low redshift but does predict less evolution at $z > 1$. Other measurements of the CSFH at $z < 1$ are broadly similar (e.g., Hopkins, 2004). Given the results of our cross checks and consistency with the literature, we conclude our approach to measuring radio luminosity function is valid.

6 CONCLUSIONS

We have measured the CSFH at $z < 1.3$ of 918 star forming galaxies in the COSMOS field with 1.4 GHz radio continuum flux densities of $S_{1.4} > 40 \mu\text{Jy}$. We find that just 9% of the radio sources from the VLA-COSMOS Large Project radio catalogue do not have optical counterparts down to a magnitude limit of $I = 26.5$. We have also increased the size and depth of our sample by using radio flux densities measured at the positions of $I < 26.5$ galaxies selected from the COSMOS optical catalogue.

We find that our radio measurements of the CSFH,

^aThis volume includes the outer region with the shallower flux density limit.

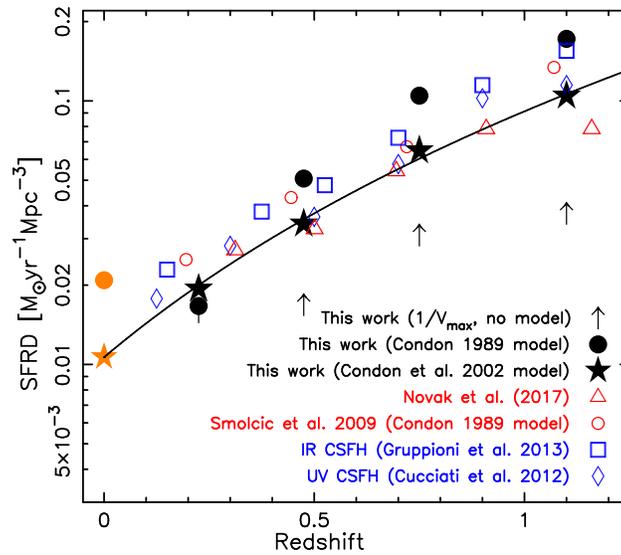

Figure 3. Our measurements of the CSFH, along with UV, IR, 3 GHz and 1.4 GHz measurements from the recent literature (Smolčić et al., 2009; Cucciati et al., 2012; Gruppioni et al., 2013; Novak et al., 2017). For clarity we do not show random uncertainties as they are comparable to or smaller than the symbols. Our SFRD measurements include lower limits determined with the $1/V_{max}$ method, estimates determined with fits of the deprecated Condon (1989) model and estimates determined with fits of the preferred Condon et al. (2002) model. Measurements of the $z = 0$ SFRD, determined with the radio luminosity functions of Condon (1989) and Condon et al. (2002), are shown with the orange symbols. Our best measurement of CSFH is in broad agreement with recent UV, IR and 3 GHz results, and can be extrapolated to agree with the $z = 0$ radio luminosity function of Condon et al. (2002). Pure luminosity evolution, shown with the black line, approximates our data well and indicates the SFRD has declined by a factor of ten since $z = 1.1$.

and those from the prior literature, have increasing dependence on the LF model with increasing redshift. For example, for our high redshift bin the deprecated Condon (1989) model produces SFRD measurements that are 65% higher than those produced by the Condon et al. (2002) model. We find that pure luminosity evolution of the Condon et al. (2002) model approximates our data well, and the resulting SFRDs are in broad agreement with recent UV, IR and 3 GHz measurements. Using our preferred model and 525 $z < 1.3$ star forming galaxies, we find that the SFRD is approximated by $0.0109 \times (1+z)^{3.10 \pm 0.06} M_{\odot} \text{ yr}^{-1} \text{ Mpc}^{-3}$ and that it has declined by a factor of ten since $z = 1.1$.

7 ACKNOWLEDGEMENTS

We are grateful to Olivier Ilbert and Peter Capak for providing preliminary optical galaxy and photometric redshift catalogues during the development of this paper. MJIB acknowledges financial support from The Australian Research Council (FT100100280), the Monash Research Accelerator Program (MRA), the Monash Outside Studies Programme (OSP) and the University of Cambridge. Part of this work was undertaken while MJIB was on OSP (sabbatical) leave at the University of Cambridge, Swinburne University and the University of Melbourne. The National Radio Astronomy Observatory is a facility of the National Science Foundation operated under cooperative agreement by Associated Universities, Inc.
